

## HEPATITIS C

Information, advice, testing,  
support & training service

### More about cirrhosis

The term cirrhosis is derived from the Greek term scirrhus and is used to describe the orange or tawny surface of the liver. Chronic hepatitis C infection can lead to liver damage, through the development of fibrosis (scarring) tissue in the liver. After years or decades of constant assault by the hepatitis C virus, liver fibrosis can become so extensive that the architecture of the liver is altered as a result of excessive scarring, development of small nodules, and changes in liver tissue. This is called cirrhosis.

As cirrhosis further develops, scar tissue replaces healthy liver cells and the ability of the liver to perform its many functions is impaired. It is important to remember that the majority of people with hepatitis C **do not** develop cirrhosis. Hepatitis C is a slowly progressive disease and only about 10-25% of people with chronic hepatitis C develop cirrhosis, but this process usually takes many years or decades.

Cirrhosis is divided into two categories—compensated and decompensated.

#### **Compensated Cirrhosis**

Compensated cirrhosis means that the liver is heavily scarred but can still perform many important bodily functions. Many people with compensated cirrhosis experience few or no symptoms and can live for many years without serious complications. But it is important to remember that HCV disease progression is not linear; that is, the process speeds up so it is critical for people to take the necessary steps to make sure that they are receiving the appropriate medical care, which may include HCV therapy to help slow down or stop the disease progression process.

#### **Decompensated Cirrhosis**

Decompensated cirrhosis means that the liver is extensively scarred and unable to function properly. People with decompensated cirrhosis eventually develop many symptoms and complications that can be life threatening.

#### **Symptoms and Complications of Decompensated Cirrhosis**

Patients with decompensated cirrhosis develop a variety of symptoms such as fatigue, exhaustion, loss of appetite, nausea, jaundice, weight loss, stomach

pain, impotence, bruising and bleeding, and other potentially life threatening symptoms.

Complications will also develop because the liver is unable to perform many functions.

### **Complications can include:**

- A combination of factors such as portal hypertension, low albumin levels and kidney dysfunction produce an accumulation of fluid in the body. Ascites is the accumulation of fluid in the abdominal cavity. Edema is the accumulation of fluid in the extremities, especially the feet and legs.
- Bleeding problems (coagulopathy) develop as the liver is unable to produce clotting factors. In addition platelet (for blood clotting) count drops because of an enlarged spleen.
- As liver disease progresses there is bone mass and density loss.
- The spleen stores red and white blood cells and platelets. An enlarged spleen develops due to blood being forced into it when portal hypertension develops. An enlarged spleen loses its ability to store red and white blood cells, and platelets.
- Hardening of the Liver due to dying liver cells can be felt on examination.
- A damaged liver is unable to regulate the production and breakdown of some female and male hormones. In women this can cause menstrual irregularities, and in men, gynecomastia (breast enlargement).
- Impaired Mental Status is due to many factors. Toxic substances that are usually filtered by the liver reach the brain. Symptoms of encephalopathy include personality changes, changes in sleep patterns, sluggish movements, drowsiness, confusion, stupor, and coma.
- Itching (pruritus) can develop that can be debilitating. The cause of pruritus is believed to be caused by impairment or failure of bile flow complicated by jaundice.
- Kidney function deteriorates in someone with decompensated cirrhosis, contributing to fluid retention (ascites, edema) and various kidney disorders.
- People with hepatitis C who develop cirrhosis are at risk for liver cancer.
- Muscle wasting can result from the liver's inability to metabolize proteins, which can make a person with cirrhosis more prone to bone fractures.
- Scar tissue in the liver restricts the flow of blood and leads to portal hypertension resulting in complications such as ascites, spontaneous bacterial peritonitis, varices and other potentially life-threatening complications.
- Spontaneous Bacterial Peritonitis is a condition caused when the body's natural bacteria enters the ascites fluid causing severe infection.
- The veins in the stomach, esophagus and rectum become so stretched and dilated (due to portal hypertension) that a condition called varices develops which can lead to internal bleeding.

When the liver completely breaks down and is unable to perform its job, it is called end-stage liver disease. The goal at this stage is to try to manage complications due to a deteriorating liver.

Unfortunately, antiviral treatment is not recommended for people with decompensated cirrhosis because HCV therapy can accelerate the decompensation process. Currently, the only potentially effective treatment for end-stage liver disease is liver transplantation.
